Abstract

We present a new multigrid scheme for solving the Poisson equation with Dirichlet boundary conditions on a Cartesian grid with irregular domain boundaries. This scheme was developed in the context of the Adaptive Mesh Refinement (AMR) schemes based on a graded-octree data structure. The Poisson equation is solved on a level-by-level basis, using a “one-way interface” scheme in which boundary conditions are interpolated from the previous coarser level solution. Such a scheme is particularly well suited for self-gravitating astrophysical flows requiring an adaptive time stepping strategy. By constructing a multigrid hierarchy covering the active cells of each AMR level, we have designed a memory-efficient algorithm that can benefit fully from the multigrid acceleration. We present a simple method for capturing the boundary conditions across the multigrid hierarchy, based on a second-order accurate reconstruction of the boundaries of the multigrid levels. In case of very complex boundaries, small scale features become smaller than the discretization cell size of coarse multigrid levels and convergence problems arise. We propose a simple solution to address these issues. Using our scheme, the convergence rate usually depends on the grid size for complex grids, but good linear convergence is maintained. The proposed method was successfully implemented on distributed memory architectures in the RAMSES code, for which we present and discuss convergence and accuracy properties as well as timing performances.

Keywords: Poisson equation; Multigrid methods; Adaptive mesh refinement; Elliptic methods

1. Introduction

Elliptical partial differential equations play a central role in many mathematical and physical problems. The Poisson equation, in particular, arises naturally in the context of electromagnetism, fluid dynamics and gravity. It is therefore of great significance in astrophysics, of which those fields are essential theoretical aspects. In the classical Newtonian limit, one can relate the gravitational potential Φ to the matter distribution (local density) ρ by:

$$\Delta\Phi = \rho \tag{1}$$

Applications in computational astrophysics therefore often require solving a discretization of Eq. (1) on some discrete grid. The ubiquity of the Poisson equation in science has led to the development of many suitable numerical solving techniques, for a wide range of specific applications and problems.

In some cases, one can solve for the discretized potential directly from Eq. (1): the convolution theorem allows to solve the Poisson equation directly in Fourier space using the Green function of the Laplacian operator on the grid of interest. In computational applications, this is usually done using the Fast Fourier Transform (FFT), which is particularly suited to periodic boundary conditions problems on rectangular, regular grids. This direct method is very effective: on a grid of linear size N , the computing time in 3 dimensions is of order $\mathcal{O}(N^3 \log N)$, and yields the solution to the discretized problem within numerical roundoff accuracy. The Green function method can be generalized to non-periodic boundary conditions and adaptive grids on rectangular domains [see e.g. 8].

Another class of Poisson solving schemes are relaxation methods, such as Gauss-Seidel or successive over-relaxation (SOR) [see e.g. 22]. Unlike the Green function method, those schemes are iterative, and rely on an initial estimate (“first guess”) of the solution. The estimate is then successively improved by iterative damping of the residual $r = \Delta\Phi - \rho$. Relaxation methods are generally simple to implement, and suitable for a wide range of elliptic problems. Methods such as Gauss-Seidel or SOR only require the forward computation of the differential operator, which is usually inexpensive, and makes it possible to use such relaxation methods on complex grid geometries. Krylov subspace methods [see e.g. 25], such as the Conjugate Gradient (CG) method, are another class of iterative methods which can be used to solve Eq. (1) in the form of the optimization problem:

$$\min_{\Phi} \|\Delta\Phi - \rho\|^2 \tag{2}$$

Classical iterative methods have gained in interest in the last decade with the advent of massively parallel computing. They only require one-cell thick, boundary layer from the neighboring processor, while FFT involves a massive transpose of the whole volume of data. Moreover, one does not need the exact solution of the discretized Poisson equation that the FFT provides: the error in the solution is already dominated by truncation errors of a fraction of a percent for practical applications. Iterative methods can therefore be stopped quite early, when the residual norm has dropped well below the truncation errors. Still, classical iterative methods can be very time consuming, especially when the grid size is increased. Usually, the large scale modes are the slowest to converge, and the number of iterations required to reach a given level of residual usually increases with the number of grid points per dimension [22].

The convergence rate of iterative relaxation methods, such as Gauss-Seidel, can be dramatically improved by multigrid acceleration [2, 31]. Multigrid methods use a hierarchy of discretizations of decreasing spatial resolution. At the resolution of the initial problem (on the finest grid), the solution is iteratively improved by subtracting corrections obtained from the coarser grids. This ensures that the large-scale modes of the residual are efficiently damped, while a traditional smoothing relaxation scheme takes care of the small-scale modes of the error. In ideal cases (e.g. for smooth problems with simple boundary conditions on rectangular domains), multigrid methods can exhibit remarkable convergence properties: the residual norm decreases at a constant rate during the whole convergence process (down to machine precision). The convergence rate can be very fast (see examples below), and more importantly *it does not depend on the size of the grid*. This last property is perhaps the most important one, since it allows one to consider very large computational problems: for a given level of convergence in the residual norm, optimal multigrid methods are linear in the problem size N^3 . This complexity is lower than the one offered by the FFT, and although multigrid is still slower than optimized FFT for small configurations, it can be quite competitive for large parallel computations and reasonable stopping criteria. In contrast to traditional iterative schemes, the convergence properties of multigrid are unaffected by the choice and quality of the first guess. Another reason to use multigrid is that it couples nicely to adaptive Cartesian grids, while FFT-based methods in this case are still possible, but quite complicated [see e.g. 4, 8, 23]. Last but not least, while FFT requires a Poisson equation with constant coefficients, multigrid methods, because they are defined in

real space, can be adapted to solve Poisson equations with non-uniform coefficients, or even non-linear equations. This property is particularly useful for problems with complex boundaries [21], multiple incompressible fluids [24], or models with modified gravity [12, 29, 15]).

The objective of this paper is to implement a simple and efficient multi-grid Poisson solver for a Cartesian grid with *arbitrary domain boundaries*. Complex boundary conditions are usually found in fluid mechanics problems featuring immersed bodies or complex multiphase flows [27, 26, 14]. Here, our motivation is different: we would like to design a Poisson solver for the class of Adaptive Mesh Refinement (AMR) codes for which the mesh is defined on a “graded octree” [13, 28, 21]. The octree mesh structure ensures that the geometry of the grid closely adapts to the properties of the flow, without the traditional overhead associated to the large rectangular patches of block-structured AMR. The consequence is however that the mesh of a given AMR level can have a very complicated shape, with holes and irregular boundaries. If one solves the Poisson equation on the whole AMR hierarchy, this translates into a modification of the Laplacian operator at fine-coarse grid boundaries, but the corresponding multigrid solver remains similar to its Cartesian grid equivalent [see e.g. 10].

In most astrophysical applications, it is however almost always impractical to solve the Poisson equation on the whole grid at once: self-gravity has the effect of dramatically increasing the dynamical range of the density field, leading to very different characteristic timescales within the same computational domain. Advancing the whole system with one single time step can be very inefficient, since only a very small fraction of the volume actually needs high accuracy in the time coordinate. This is particularly true for cosmological simulations, where most of the computational volume is covered by low density regions that evolve slowly, while a small number of highly resolved cells sample dense regions (such as galaxies), where the dynamical time scale is very short. Most AMR codes address this problem by using *adaptive time stepping*, where a given fine level is updated more frequently than its coarser level, ensuring that the actual timestep remains close to the natural CFL timestep (so that the whole AMR grid is not updated more often than needed). In RAMSES, we typically update a finer level twice as often as its coarser level. As a consequence, consecutive fine and coarse levels are only synchronized at every other fine timestep.

Whenever all the AMR levels are synchronized, it is possible to solve the Poisson equation on the whole grid at once. Such a Poisson solver is called a

“two-way interface” scheme, as the information is propagated both from the coarse grids to the finer grids and back: the coarse grids “feel” the effect of the finer grids. Many multigrid solvers have been successfully implemented in this case [10, 21, 19, 23]. Popinet [21] has developed an incompressible flow solver with complex boundary conditions, using an octree data structure. The solver features a “half V-cycle” multigrid schedule, which makes it possible to perform multigrid iterations within the existing AMR hierarchy, with no additional storage. This pioneering work, however, requires the use of a single global time step for the whole AMR grid. Most of the time, fine and coarse levels are not synchronized, and it is not possible to solve on the whole grid at once. It is therefore necessary to resort to a “one-way interface” scheme [see 9, 13, 28, 19]. In the traditional “one-way interface” approach, the AMR levels are updated separately: the coarsest level is updated first, then the computed coarse potential is used to impose boundary conditions on the finer levels, which can then be solved separately and more frequently. The gravitational potential on finer AMR levels is solved by imposing Dirichlet boundary conditions at the finer level boundary, enforcing potential continuity. Because we are dealing with an arbitrarily complex octree structure, we must be able to solve the Poisson equation on a given refinement level with arbitrarily shaped domains. The problem we would like to address here is therefore to solve the Poisson equation using the multigrid method, with the constraint that Dirichlet boundary conditions are imposed on the outer cell faces of an arbitrary domain (see Fig. 1). Note that using adaptive time stepping and one-way interface poses a time synchronization problem: as the finer levels are stepped forward, the boundary conditions derived from the coarser levels fall out of synchronization with the time at finer levels. The problem of non-synchronized AMR levels has been approached in the context of incompressible flows [17] and coupled collisional and collisionless systems for cosmological applications [19]. A proposed solution is to update the coarse levels first and obtain the fine boundary conditions by both time and space interpolation of the coarse values. However, this requires storing the time derivatives of the potential at every level. In addition, in order to obtain a fully multilevel solution, the coarse levels should take into account the solution on the finer levels. Whenever the coarse levels are updated first, it is therefore necessary to correct their values with an estimate of the difference between the single level and multilevel solutions, before the finer levels are updated. Such an approach has been used for example by Martin and Colella [17], Miniati and Colella [19] in order to provide corrected coarse

boundary conditions for the time interpolation. RAMSES uses a different approach: finer levels are updated first, using as boundary conditions values which are not extrapolated in time but fixed at the initial coarse time step. Once the fine levels have been stepped forward in time, RAMSES updates the matter density in the coarse cells by binning the fine children cells into the coarse level density with a CIC scheme around their center of mass. The information from the fine evolution thus flows back up to the coarse levels. This scheme, however, does not guarantee the time accuracy of the time interpolation and correction methods. Note that the solver presented in this paper applies equally well to any scheme used to derive the boundary conditions, as it handles each AMR level independently.

As Cartesian grids are much more practical than unstructured meshes, the accurate description of boundaries immersed in Cartesian grids have been the focus of much effort, especially in computational fluid dynamics [see e.g. 1, 32]. This approach has also led to the development of sophisticated Poisson solvers, some relying on multigrid acceleration [10, 18].

Our goal is to present a simpler but efficient solver, suitable in particular to the case of tree-based AMR codes with a one-way interface scheme. We will apply our new scheme to the AMR code RAMSES, a self-gravitating fluid dynamics code for astrophysical applications [28]. The octree structure is based on the “Fully Threaded Tree” approach proposed by Khokhlov [11] for which cells are split into “octs” (groups of 8 cells) on a cell-by-cell basis [13, 28]. The paper is organized as follows: we first describe our basic multigrid algorithm for the Poisson equation with Dirichlet boundary conditions. We then detail how we capture complex boundary conditions at coarse multigrid levels within our framework. We report a very fundamental issue of our approach (namely the “small islands” problems) and we propose a simple fix to overcome it, and we finally discuss the performance of our algorithm.

Note that we only address the issue of the boundary reconstruction for coarsened multigrid levels: for one-way interface AMR applications, at the finest level (i.e., the AMR level to solve), the boundary is usually located along faces of Cartesian grid cells constituting the fine AMR level, and no cut-cell or level set reconstruction is needed in this case. However, we believe our method can be adapted to a cut-cell or level set boundary at the fine level, provided an appropriate fine operator is defined.

2. A Multigrid algorithm for complex boundary conditions

Multigrid methods combine a relaxation solver (usually a smoother such as Gauss-Seidel or Jacobi sweeps) and a multi-resolution approach, to ensure efficient damping of both small and large scale components of the residual (see for example [31] for an introduction).

For one-way interface schemes (in the RAMSES code for example), the Poisson equation is solved over the whole AMR hierarchy on a level-by-level basis, the size of the cell involved in each individual Poisson solve being uniform. Each AMR level constitutes the finest level of the multigrid hierarchy. The finest multigrid level is therefore defined by a Cartesian grid with complex irregular boundaries. We then build a hierarchy of coarser grids which cover this reference domain (see Fig. 2 for an illustration). This new hierarchy defines the multigrid structure for the current level. Although it is also based on an octree structure similar to the underlying AMR grid, it is a different structure that does not interfere with the coarse AMR levels (which are, in a way, “orthogonal” to the multigrid levels).

One major advantage of using this secondary grid hierarchy for each Poisson solve is that the computational cost of the multigrid solver at a given level only scales as the number of cells in that level, as we use only a subset of the AMR coarser cells. This is especially crucial for astrophysical problems, where fine grids can occupy a fraction of the volume much smaller than the coarser levels.

Let us consider the Poisson problem, discretized on a fine grid domain Ω_f :

$$\begin{aligned} \Delta_f \Phi_f &= \rho_f \quad \text{on } \Omega_f, \\ \text{Dirichlet conditions} &\quad \text{on } \partial\Omega_f. \end{aligned}$$

where the f subscripts denote the discretized Laplacian operator and fields on the fine grid. For a single multigrid iteration, we follow the traditional recipe:

1. Perform N_{pre} Gauss-Seidel smoothing passes on the current estimate Φ_f of the fine solution,
2. Compute the fine residual

$$r_f \leftarrow \Delta \Phi_f - \rho,$$

Figure 1: Poisson problem at the fine level for a given AMR level. The solution potential to be determined is defined at the cell centers (dots). The boundary conditions are defined at the border cell faces (crosses). The boundary values are linearly interpolated from the solution at the coarser AMR level (not represented), which was previously computed because of the one-way interface scheme.

Figure 2: Levels of the multigrid hierarchy for the problem of Fig. 1.

3. Compute the fine-to-coarse restrictions of the solution and residual:

$$\begin{aligned}\Phi_c &\longleftarrow R(\Phi_f) \\ r_c &\longleftarrow R(r_f),\end{aligned}$$

4. Define a coarsened domain Ω_c and boundaries $\partial\Omega_c$ from Ω_f . The prescription for deriving $\partial\Omega_c$ from the fine level is the key issue, and will be discussed in section 3.
5. Compute a coarse correction $\delta\Phi_c$, by performing N_{cycles} multigrid iterations for the following coarse problem:

$$\begin{aligned}\Delta_c(\delta\Phi_c) &= -r_c \quad \text{on } \Omega_c \\ \delta\Phi_c &= 0 \quad \text{on } \partial\Omega_c,\end{aligned}$$

6. Prolong $\delta\Phi_c$ into a fine correction

$$\delta\Phi_f \longleftarrow P(\delta\Phi_c),$$

7. Correct the fine level solution

$$\Phi_f \longleftarrow \Phi_f + \delta\Phi_f,$$

8. Perform N_{post} smoothing passes on Φ_f .

This multigrid iteration is repeated on the fine grid until the norm of the fine residual is considered small enough. To fully specify the scheme, one needs to specify integers N_{pre} , N_{post} and N_{cycles} , the restriction and prolongation operators R and P , and the discretization of the Laplacian operator.

In our case, we have found $N_{pre} = N_{post} = 2$ to yield the best performance in terms of solver time for our applications in RAMSES. We will now discuss the prolongation, restriction and discretized Laplacian operators. We postpone the discussion of the parameter N_{cycles} to section 5.3.

We use a finite difference approach to discretize the Poisson equation on the Cartesian grid. Inside the domain, away from the boundaries, we use the standard 7-point discretization of the Laplacian operator:

$$(\Delta\Phi)_i = \frac{1}{(\Delta x)^2} \sum_{\{i,j\}} (\Phi_j - \Phi_i) \quad (3)$$

Figure 3: Common first-order and second-order (respectively left and right) restriction and prolongation schemes (respectively top and bottom). R_1 simply averages the values of the subcells to obtain a coarse value. P_1 assigns the same coarse value to the all the fine subcells (straight injection). Our multigrid scheme uses R_1 and P_2 .

where the sum extends over all the 6 pairs $\{i, j\}$ of neighboring cells, and Δx is the size of the cells on which the Laplacian is evaluated. This Laplacian operator is second-order accurate and our multigrid implementation is currently restricted to this case.

For the relaxation smoother, we use a Gauss-Seidel smoother with red-black ordering, with the Laplacian operator as defined above. With red-black ordering, the cells are updated in two passes, each pass running over a half of the domain following the colors of a checkerboard pattern.

Prolongation and restriction operators define how the problem is down-sampled to a coarser level (restriction) and how the coarser level correction is interpolated back to the finer level (prolongation).

A common rule of thumb for the choice of prolongation and restriction operators for the Poisson equation is the order condition $n_P + n_R > q$, where

n_P and n_R are the prolongation and restriction operator orders, respectively, and q is the order of the Laplacian operator [see 31, 22]. Simple standard operators are shown in Figure 3. Straight injection is defined as $P1$, while its transpose, $R1$, boils down to a simple averaging. These operators are first-order in space ($n_R = 1$ and $n_P = 1$). Second-order schemes can be easily designed, like trilinear interpolation (noted here $P2$) and its transpose ($R2$), whose weights are shown in Figure 3.

We have settled for simple averaging for restriction ($R1$), and linear interpolation ($P2$) for prolongation (see Fig. 3), as this choice turned out to yield the best convergence rates for the classes of grids which we have studied. Additionally, as will be discussed in Section 4, picking simple averaging as the restriction operator turns out to be particularly convenient in conjunction with our prescription for boundary representation.

3. Second-order multigrid boundary reconstruction and the modified Laplacian operator

In our multigrid algorithm, the key ingredient is the mathematical representation of the domain boundary at coarse multigrid levels. Because our goal is to take advantage of the Cartesian grid structure of the AMR scheme, we restrict ourselves to Cartesian grid interface capturing techniques. Among the many different solutions proposed in the literature, the cut cell [10] and the level set [27, 20, 7] approaches stand out as simple and efficient techniques for interface reconstruction. The multigrid algorithm for complex boundary we propose here can be easily implemented with any of these techniques as the basic interface reconstruction scheme.

In what follows, we however simplify the problem even further, since we work in the framework of a one-way AMR Poisson solver. At the finest level (i.e., on the actual grid where the Poisson equation is to be solved), the boundaries $\partial\Omega$ are simply positioned at the faces of the outer cells themselves. In the level set approach, the boundary could have been placed at the zero level of some interpolated distance function [see e.g. 7]. Since computing distance function comes with a cost, we have considered here a simpler approach based on a coloring scheme: inner cells are initialized with a mask function with value $m_i = 1$ and outer cells with a mask $m_i = -1$. The domain boundary $\partial\Omega$ is defined at the position where the interpolated value of the cell-centered mask ($m_i \in [-1, 1]$) crosses zero. At the finest multigrid level, these interpolated positions are at the cell faces, as desired.

Figure 4: The Laplacian stencil near boundaries: the center of the leftmost cell lies outside the domain, and therefore has a negative mask value $m < 0$. For this cell, a ghost value will be reconstructed as shown on Fig. 5. For all the three other cells, the actual cell center values are used unchanged.

We now compute the mask value at coarser multigrid levels by simply averaging recursively the mask value at the finest level (as for the residual). Here again, if one wants to use a distance function to capture the boundary, one could compute the coarser representation of the distance function also by simple averaging. At each level ℓ in the multigrid hierarchy, the domain Ω^ℓ is defined as the set of cells for which $m_i^\ell > 0$. The use of the R1 operator maintains the correct location of the boundary as much as possible, without spreading the boundary information too much across neighboring coarse cells.

In order to reconstruct the location of the multigrid boundary, and solve for the corresponding Poisson problem, we use a prescription similar to the one described in Gibou et al. [7]. The idea is to redefine the Laplacian operator close to the domain boundary. Whenever one of the neighboring Φ_j has $m_j \leq 0$ (and therefore lies outside Ω , see Fig. 4), it is replaced by a ghost value $\tilde{\Phi}_j$ linearly extrapolated from Φ_i and the boundary value. This ghost value depends explicitly on Φ_i and the boundary condition. A 1D illustration is presented on Figure 5. Since this prescription uses a linear reconstruction for the multigrid boundary in each direction, the boundary position is recovered at second order spatial accuracy. As in [7], the boundary is positioned in each direction independently, and the 1D case trivially generalizes to 3D.

The coarsening of the boundary from $\partial\Omega_f$ to $\partial\Omega_c$ is now fully specified by the restriction operator used for the mask m_i and by the modified Laplacian closed to the boundary. These are the 2 key ingredients in our multigrid scheme: the boundary remains at the same location (up to second order in space) when we go from fine to coarse levels in the multigrid hierarchy. The boundary condition $\Phi = 0$ is therefore imposed at the correct location, so

Figure 5: Reconstruction of ghost cell values across boundaries. Cells with negative mask (white dots at centers) are outside of the domain and do not carry a valid Φ value. The computation of the Laplacian at cell i requires the use of a ghost value $\tilde{\Phi}_{i-1}$ which is obtained from Φ_i by linearly extrapolating the boundary condition. In accordance with the level set idea, the boundary is positioned at the point where m crosses zero, which is found by linearly interpolating the mask values.

that the coarse solution of the Poisson equation with the coarse boundary corresponds to the solution of the Poisson equation at the finer level with the fine representation of the boundary.

We speculate that the chosen multigrid boundary reconstruction scheme should satisfy an order condition similar to the prolongation and restriction operators [31, 22]. Although a mathematical proof is beyond the scope of this paper, our numerical experiments suggest that this is indeed the case. We see in Figure 7 that, in case of a smooth boundary, our second-order multigrid boundary reconstruction scheme results in a perfect multigrid convergence¹, while the first-order scheme doesn't. As we will now discuss, in case of very complex boundaries, second-order reconstruction of the multigrid boundary is not possible anymore, and we have to degrade our scheme to first-order to ensure convergence.

4. First-order multigrid boundary reconstruction and the “small islands” problem

We see in Figure 7 that a different type of boundary can lead to a catastrophic divergence of our multigrid scheme (the blue line shows the residual norm evolution in case of second-order multigrid boundary reconstruction).

¹Multigrid convergence means here that the damping rate of the residual norm does not depend on the grid size.

Figure 6: Coarsening (restriction) may cause loss of boundary conditions. The Dirichlet BCs around an isolated cell with $m = -1$ among a sea of $m = 1$ cells are lost after one coarsening step, as the resulting coarse mask is positive everywhere.

This rather complex boundary condition is typical of AMR grids in cosmological simulations [28]. It features many small disconnected domains that cluster in a large central region with many “holes”. Successive coarsening of the grid resolution leads in this case to a loss of boundary conditions, especially when “holes” or “small islands” are present. Indeed, in this case, the finer boundary small scale features cannot be represented anymore on coarser grids. Figure 6 illustrates such a case, for which the fine grid still has a cell with a negative mask value, so that the $\Phi = 0$ boundary condition still applies, but the coarse grid has cells with only positive values. Because of this topological change in the boundary representation, the coarse and fine solutions of the Poisson equation become significantly different. Spurious eigenmodes associated to this loss of constraints at the boundary are not damped quickly enough by the smoothing operator at the fine level: this leads to slower convergence rates and, in some case, to catastrophic divergence (see Fig. 7).

One previously proposed solution to this problem is the subtraction of the divergent modes introduced by these small islands, for example by recombining the multigrid iterants [3]. This however turns out to be too computationally and memory intensive for us to use in the Poisson solver of the RAMSES code: it requires storing a large number of previous solutions. This recombination method also tends to perform worse when the number of islands increases, which would likely render it useless in the case of the complex grid structure encountered in cosmological simulations.

Another proposed solution is to stop coarsening the residual in the multi-

grid hierarchy whenever such a problem occurs during multigrid coarsening [10]. This degrades the performance of the multigrid method, since large scale modes are no longer damped efficiently. In the case of very complex boundaries with small islands, like in Figure 7, the level at which the hierarchy has to be truncated is so close to the finest level that the whole multigrid approach breaks down.

In order to overcome these limitations, McCorquodale et al. [18] proposed to keep track of the boundary representation at the fine level, and modify the Laplacian on coarse grids, whenever the operator stencil crossed this fine boundary. Stencil nodes which cannot be reached from the stencil center by a straight segment without crossing the boundary are excluded, and an asymmetric stencil is used, chosen in function of the local configuration of the interface.

We propose here a simpler approach, based on the observation that these small islands correspond to local minima in the color function m_i (or equivalently in the distance function if needed). The averaging scheme will tend to smooth these extrema, resulting in the disappearance of the negative values (see Fig. 6) and in the apparition of spurious boundary conditions. In analogy to traditional high-order numerical schemes for hyperbolic systems of conservation laws [30, 5], we solve the problem by switching *globally* to a first-order multigrid boundary reconstruction scheme. We impose the $\Phi = 0$ constraint at the coarse level on the grid point nearest² to the interface: in practice, for each cell for which the mask value $m_i < 1$, we impose $\Phi_i = 0$. The simple averaging restriction for the mask ensures that cell i has $m_i < 1$ if and only if it has a non-zero intersection with the boundary.

We have tested our first-order multigrid boundary reconstruction scheme on 2 extreme types of boundary conditions : a simple disk with no hole or island, and a complex clustered grid, typical of AMR cosmological simulations. We have compared its convergence properties to the second-order reconstruction scheme in Figure 7. In the disk case, the simple topology of the boundary allows us to take full advantage of the second-order reconstruction of multigrid boundaries, resulting in fast convergence rates (in blue), totally independent of the problem size. This shows that our overall scheme features a true “textbook” multigrid convergence. Using the first-order multigrid boundary reconstruction, we degrade the convergence rate

²The so-called NGP scheme for Nearest Grid Point.

Figure 7: L_2 norm of the residual as a function of iteration number in our multigrid Poisson solver in 2D for both presented boundary capturing schemes. For each domain shape shown in the insets, the residual for both 2nd order (in blue) and 1st order (in red) boundary capturing schemes is presented for a 64^2 grid up to a 1024^2 grid.

significantly, and it now depends slightly on the problem size. This is expected since the position of the boundary at two consecutive multigrid levels can differ by half a cell width, and this first-order error in the boundary positioning limits the accuracy of the coarse correction.

In the complex boundary case, with many holes and islands, our second-order reconstruction fails, as we can see from the divergent behavior of the residual norm in Figure 7. We interpret this catastrophic behavior as follows: topological changes in the boundary representation at coarse levels result in spurious long-range mode that are not damped by the smoothing operators at finer levels. If we use first-order multigrid boundary reconstruction, we observe that the convergence is restored: although first-order reconstruction of the boundary introduces small-scale errors close to the boundary, these errors are efficiently damped by the smoothing operator at finer levels. Note however that the convergence rate is slower than in the disc case, and that the convergence rate now depends on the grid size. A similar effect was observed in [6, 21].

Note that in our present implementation, we have to decide beforehand to which order we wish to reconstruct the multigrid boundaries. We have tried to implement an adaptive algorithm, for which the reconstruction scheme is

adapted locally to the topological changes of the boundary, but no satisfactory results were found. This then raises the question: how do we choose between first or second order reconstruction, when solving the Poisson equation on an arbitrarily complex grid? It may be possible to decide from a topological analysis of the grid (such as its genus and the number of connected components), but this proves difficult to achieve in practice.

We have opted for a pragmatic approach, and decide at run time which scheme to employ for each AMR level independently. When we start solving the Poisson equation on a given level, we first try using the second-order reconstruction. We monitor the convergence rate during the iterations, and if it becomes slower than a fixed threshold, i.e. if $\|r_{n+1}\|_2 / \|r_n\|_2 > \eta$ with typically $\eta = 0.5$, we switch to the first-order scheme for that level only and for the next 10 solves. With our current implementation, if the AMR grid is really complex (with small islands), the solver only wastes a couple of iterations before deciding on which of first or second-order gives the best convergence rate. This works very well in practice, even in cosmological simulations featuring clusters and filaments, as only a few intermediate AMR levels exhibit very complex topologies.

5. Accuracy and performance tests

5.1. Accuracy tests

We have tested the accuracy of the solver by comparing numerical solutions computed using RAMSES to exact analytical expressions. We chose a 2D setup inspired from galaxy simulations, with a radial mass distribution centered in the computational box. With coordinates $(x, y) \in [0, 1]^2$ the radial coordinate is given by $r^2 = (x - \frac{1}{2})^2 + (y - \frac{1}{2})^2$. We take the analytic potential $\Phi_e(r)$ —subscripted with e for exact—to be

$$\Phi_e(r) := \ln \left(\left[\frac{r}{r_0} \right]^2 + 1 \right), \quad (4)$$

which is smooth everywhere in the domain and features a core at the origin. The parameter r_0 controls the concentration of the profile. The corresponding density profile $\rho_e(r)$ is obtained from (1):

$$\rho_e(r) = \frac{4r_0^2}{(r^2 + r_0^2)^2}, \quad (5)$$

which is positive and smooth everywhere. The analytical expression for the force intensity $f_e = |\nabla\Phi|$ is

$$f_e(r) = \frac{2r}{r^2 + r_0^2}, \quad (6)$$

and the force vector everywhere points towards the center of the box. The boundary conditions at the border of the computational box are set using the exact solution (4).

Using this setup, we have computed the truncation error for the potential and the force as a function of the finest grid resolution for both a Cartesian grid and an AMR grid with 3 additional AMR levels. For the resolution level ℓ , the finest cell size Δx in the grid is given by $\Delta x = (1/2)^\ell$. We use a quasi-Lagrangian mesh refinement strategy, closest to what is commonly employed in astrophysical applications: given a fixed threshold mass M , each cell containing a mass exceeding $2^{N_{\text{dim}}}M$ is refined (split) into $2^{N_{\text{dim}}}$ children cells.

In our test, whenever the resolution is increased by 1, the base (coarsest) AMR level is incremented by 1, and the mass resolution M is divided by 4 (in 2D). This procedure allows us to increase the resolution of the finest AMR cells by exactly one level, while keeping the depth of the AMR grid a constant. We initially pick the value of M such that it triggers the refinement of 3 AMR levels. The resulting grid for resolution level 7 is shown on Fig. 9.

We have evaluated the truncation errors for both the potential and the gravitational force in order to test the one-way interface scheme. Once a solution for the potential has been obtained at for a given AMR level, RAMSES computes the force for this level using a 5-point finite difference approximation of the gradient:

$$\partial_x \Phi = \frac{4}{3} \frac{\Phi_{i+1} - \Phi_{i-1}}{2\Delta x} - \frac{1}{3} \frac{\Phi_{i+2} - \Phi_{i-2}}{4\Delta x} + \mathcal{O}((\Delta x)^4) \quad (7)$$

The truncation errors are presented on Fig. 8. For the potential, both Cartesian and AMR grids feature second-order convergence. For a given resolution level, the AMR truncation error is larger than the corresponding Cartesian error: this is expected, since AMR will only use the maximal resolution in particular areas of the grid, leading to bigger truncation errors because of the presence of coarser cells.

Figure 8: Truncation error on the potential (left) and force (right) for the setup described in the text, as a function of the maximal resolution level ℓ . The finest cell size Δx is given by $\Delta x = (1/2)^\ell$. The solid lines are $\mathcal{O}(\Delta x^2)$ (second order), the dashed line is $\mathcal{O}(\Delta x)$ (first order), and the dotted line is $\mathcal{O}(\Delta x^{1.6})$.

Figure 9: AMR grid in the accuracy test case described in the text, at resolution level 7. The base grid is at level 4, with 3 AMR levels reaching down to level 7 using a quasi-Lagrangian refinement strategy.

Figure 10: Computation of the gravitational force in RAMSES using the finite difference approximation (7). At a fine-coarse interface, the missing fine values (empty circles) are computed from the coarse level potential by linear interpolation. Prior to solving for Φ at the fine level, the boundary values for the fine Poisson problem (blue crosses, see also Fig. 1) had been computed in the same manner.

Similarly to the potential, in the Cartesian case, the truncation error of the force decreases at second order. In the AMR case however, the convergence is degraded to first order for the L_∞ norm. We attribute this effect to the one-way interface scheme. Whenever the finite difference approximation of the gradient crosses the level boundary, RAMSES fills in the missing values by linear interpolation from the coarser level, as illustrated on Fig. 10. Since the coarse Laplacian operator and linear interpolation are both accurate to second order, the interpolated values (empty circles on Fig. 10) have a truncation error of the form $(\Delta x)^2 \epsilon_i$, where $\epsilon_i = \mathcal{O}(1)$. Note that ϵ_i accounts for both the coarse Laplacian and interpolation errors. The valid values at the fine level (solid dots on Fig. 10) are accurate to second order, with a truncation error $(\Delta x)^2 \eta_i$, with $\eta_i = \mathcal{O}(1)$. Across the interface, the truncation error jumps abruptly from $(\Delta x)^2 \epsilon_i$ to $(\Delta x)^2 \eta_i$. Since there is no reason for ϵ_i and η_i to connect to the same value at the coarse-fine boundary, the difference formula (7) will produce a $\mathcal{O}(1/\Delta x)$ spike on the derivative of these terms. This translates to a $\mathcal{O}(1/\Delta x)(\Delta x)^2 = \mathcal{O}(\Delta x)$ error on the gradient of Φ .

This problem was previously noted in the case of AMR solvers [see e.g. 16, for a discussion for an AMR Poisson solver], and is inherent to the one-way interface scheme. It could be avoided using higher order Laplacian and interpolation operators. Using third order operators would reduce the error at the interface to $\mathcal{O}(\Delta x)^2$.

Fig. 11 represents the local force error as a function of cell radius for

Figure 11: Relative error on the force in the 3-level setup described in the text, at resolution level 8. The values at cell centers are colored by level correspondingly to Fig. 9. On the left panel, the border potential at fine-coarse boundaries is interpolated from the coarser level, as implemented in RAMSES with the one-way interface scheme. The interpolation results in a degradation of the force to order 1 within shallow regions around the AMR level transitions. On the right panel, the border potential is obtained from the analytic solution, illustrating a best-case solution on the given grid.

the test problem at resolution level 8. The left panel shows the RAMSES prescription using interpolation for computing potential and force at level boundaries, according to Fig. 10. In the right panel, the missing potential values for both boundary conditions and force computation are no longer interpolated from the coarse level, but rather evaluated directly from the exact analytic solution, which suppresses any truncation error problem at the level interfaces. The comparison of the two panels shows that the impact of the one-way interface scheme on the global quality of the solution is minimal: The local force error never exceeds about 1%, and the first order degradation of the force is confined to thin shells of codimension 1. As a result, the L_2 convergence of the force is still close to order 2, scaling approximately as $\Delta x^{1.6}$ (see Fig. 8).

Note that although this test case is simple, it provides valuable insight on the properties of the one-way interface scheme coupled to the computation of the force. In the case of RAMSES, extensive tests of force in the code had been made for cosmological simulations in Teyssier [28] using the original Poisson solver. Errors on the force due to the one-way interface AMR were

typically found to be within 1%. Since the Laplacian operator is identical *at the fine (AMR) level* in our multigrid implementation to the one used for these tests, our solver would yield exactly the same solution when fully converged to numerical accuracy.

Finally, we have tested the convergence and accuracy of the solver in the presence of gradients at a level boundary. We used a concentrated mass distribution, given by Eq. (5) with $r_0 = 0.01$, centered in the computational box. Starting from a base resolution at level 10 (corresponding to a regular grid of 1024^2 cells), we introduced one level of refinement at level 11, delimited by a circular boundary of radius 0.25. By moving around the refined region within the box, we can probe the effect of the gradient on the solver as the central peak in the mass distribution approaches the boundary. For various positions of the refined level, we have performed multigrid iterations with our algorithm with a residual reduction factor set to 10^{-7} . The resulting truncation error for the fine level is plotted on Fig. 12 as a function of the boundary–mass center distance.

At separations greater than about $3r_0$, the gradient induced by the mass distribution has no noticeable effect on the quality of the global solution, for both the potential and the force. As the mass distribution gets closer to the level boundary however, large derivatives at the interface will introduce errors in the Dirichlet boundary condition, which will impact the quality of the solution in the whole refined region. Note, nevertheless, that in our test the force seems much less sensitive to this effect, possibly because its truncation error is already dominated by the first order term arising at level boundaries.

While this effect is inherently present in one-way interface methods, it could likely be reduced by using higher-order reconstructions of the Dirichlet boundary condition. As evidenced by the results on the force, however, it is not clear that much can be gained by such a sophistication, unless the order of the whole scheme is increased globally. Rather, these results highlight the importance of selecting suitable AMR refinement criteria. In computational astrophysics, AMR grids are often refined whenever the local density crosses a threshold. RAMSES combines such criteria with a level dilation strategy—which “grows” AMR level outwards, and helps reducing the granularity of the grid while limiting sharp variations of the mass distribution along the boundary.

In terms of convergence rate, the boundary gradient had no noticeable effect, as the solver converged in 6 or 7 iterations for all of the data points

Figure 12: Effect of the gradient at a level boundary on the quality of the fine level solution, for the potential (circles) and the force (squares). For boundary–center of mass separations greater than about $3r_0$, the location of the density peak has no sizable effect. As the peak gets closer to the boundary, stronger gradients introduce errors in the numerical potential. Note however that the errors on the force—which are dominated by the first-order terms arising at the level boundary—are comparatively insensitive to the boundary gradient.

represented on Fig. 12, yielding a convergence factor of about 10.

5.2. Performance in cosmological simulations

The new Poisson solver has by now been used in RAMSES in a variety of simulations. We present timings for our new multigrid (MG) solver on Table 1, together with corresponding timings for the conjugate gradient (CG) method, used here as a reference example of traditional iterative solvers. The timings represent the total wall clock time required to solve for the Poisson equation on the whole AMR grid, for a residual L_2 norm reduction factor of 10^{-3} . For the reference timings, we have set the initial guess of the solution to zero everywhere on the grid, for both solvers.

The tests were run on the CEA/CCRT Platine computer, consisting of BULL NovaScale 3045 units totaling 932 nodes, networked by an InfiniBand interconnect. Each node hosts 4 Intel® Itanium® 2 dual-core 1.6 GHz processors sharing 24 Gb of RAM.

Simulation A (a cosmological simulation at very early time) has a base 256^3 grid, with no additional level of refinement, on 32 processors. Simulation B is a “zoom” simulation, with a base resolution of 128^3 and successive

Type of AMR grid	PE	Resolution	N_{cells}	CG (s)	MG (s)
A. Cartesian	32	$256^3 + 0$ levels	19M	52	4.1
B. Zoom-in	64	$128^3 + 3$ levels	47M	160	15
C. Cosmology	1024	$1024^3 + 5$ levels	4.8G	2750	1070

Table 1: Poisson solver timings on three reference simulations, for conjugate gradient (CG) and multigrid (MG).

forced refinements up to a 1024^3 -equivalent zoom-in area. The cosmological computation follows the formation of a dense dark matter halo within the focus area. Simulation C is a clustered, $50h^{-1}\text{Mpc}$ box cosmological simulation at $z = 1$, with 1024^3 particles. At this level of nonlinearity, the finer AMR levels are extremely clustered, while the intermediate levels exhibit a complex topology as they follow the intermediate-density structures (walls, filaments and clumps).

All timings of Table 1 show a strong performance advantage of the multigrid method over the conjugate gradient. Additionally, during the time evolution of cosmological simulations, we witnessed that the multigrid solver convergence times are much more predictable and consistent across different runs than the conjugate gradient. We attribute this effect to the fact that the multigrid performance only depends on the topology of the grid, which changes progressively during the simulations, whereas the conjugate gradient is very sensitive to the quality of the first guess.

In the context of one-way interface solvers on AMR grids, we can significantly improve the performance of the conjugate gradient solver by computing a first guess solution based on the coarser level solution. We choose to linearly interpolate the initial guess of Φ at level ℓ from the solution at the coarser level $\ell - 1$, which has just been computed. This “multilevel” approach guarantees an initial guess of reasonable quality at a small extra cost—the cost of interpolating the solution from the coarser AMR level to the finer level. Note that for our CG implementation, iterations only take place at the finest level, and are therefore *not* multigrid-accelerated. We now discuss timings for our 3 test simulations using this improved CG solver. Since new multigrid timings have shown to be practically unchanged down to 2 digits, when using this new first guess, we only give new timings for the conjugate gradient solver.

Simulation A features a CG time between 5.8 and 23 seconds. The con-

jugate gradient timings are particularly erratic on the first few timesteps, because the first cosmological structures form at very small scale in the middle of a nearly uniform density field; therefore such small scale features are not accurately represented on the first guess obtained by interpolating the coarse solution. The number of iterations necessary to reach a given residual reduction factor is therefore high at the start of the simulation, before decreasing significantly as larger structures grow. In any case, the multigrid method performs significantly better than the conjugate gradient on cartesian grids, even though the conjugate gradient benefits dramatically from an optimal first guess, and has less overall overhead.

On simulation B, the CG solver with the new first guess takes 140 seconds. The almost tenfold performance gain of the multigrid algorithm over the conjugate gradient can be explained by the fast evolution of the matter density at the coarse levels in the early stages of the simulation. Since coarse levels use a bigger time step than finer levels because of adaptive time stepping, the potential on coarse cells—which is interpolated as a first guess for the finer potentials—is updated less frequently. The finer first guesses thus tend to be out of synchronization with the real solution, resulting in additional conjugate gradient iterations. The multigrid algorithm is much less sensitive to first guess quality, resulting in a significant advantage over the conjugate gradient. This situation shows the real strength of the new solver in the context of adaptive time stepping.

Finally, in the case of simulation C, the CG solver runs for 850 seconds, about 20% less than multigrid. Decomposing the solver time by level shows that the MG solver spends most of its time dealing with very fine and very clustered grids, at the finest end of the AMR structure. This is easily understood, as this type of grid geometries represent a worst-case scenario for the multigrid solver in terms of small islands, forcing intermediate AMR levels into the slightly less efficient 1st order capturing mode. Moreover, at this stage of the simulation, the timestep is usually extremely small, which is beneficial to the conjugate gradient as discussed in the case of simulation B. This result suggests using a hybrid scheme in practice, where one uses the new multigrid method for most levels of the AMR hierarchy except the finest ones, which can be handled by the CG solver. This method has been implemented in RAMSES.

For most astrophysical applications, it is sufficient to improve the solution on each level until the residual norm reaches about 10^{-3} times the norm of the initial solution, which is obtained by interpolation of the coarse solution.

Note that we use $N_{pre} = N_{post} = 2$. In the vast majority of practical 3D grid geometries encountered in cosmology and galaxy formation simulations, the multigrid algorithm performs 4 to 5 iterations, corresponding to convergence factors of about 4–6. We observe this behavior regardless of the resolution of the simulation, from simple 128^3 runs to full-scale simulations starting at 1024^3 with deep AMR grids. In this sense, the multigrid performance is close to textbook multigrid convergence in practical situations.

5.3. Effect of N_{cycles}

The N_{cycles} parameter controls how many multigrid iterations are performed when computing a coarse correction, at any level of the MG hierarchy. More iterations usually yield a better correction (and less multigrid iterations at the finest level before reaching tolerance), but significantly increase the cost of each iteration. One must therefore find an appropriate trade-off.

Performing more than 2 or 3 cycles is usually not desirable, because the coarse problem is only itself an approximation of the fine correction problem. We have studied $N_{cycles} = 1$ (“V-cycles”), $N_{cycles} = 2$ (“W-cycles”) and $N_{cycles} = 3$. We have measured the residual reduction rate and the total solver time to solve to a given accuracy (10^{-10} in our tests) for a simple disk domain as shown on Figure 7.

Typical results are presented on Figure 13. The first conclusion is that V-cycles are very sensitive to the chosen boundary reconstruction scheme. First-order multigrid boundary reconstruction is clearly detrimental to the convergence rate, though it does ensure convergence of grids with small islands. Interestingly enough, schedules with $N_{cycles} \geq 2$ (like W-cycles) appear to be insensitive to the order of the boundary reconstruction scheme. This suggests that first-order multigrid boundary reconstruction used in conjunction with W-cycles would ensure a convergence of the solver as fast as the second-order scheme. Since W-cycles have more costly iterations, we see in Figure 13 that this additional cost translates however into a longer overall time. For most astrophysical applications we have explored with the RAMSES code, we have found that V-cycles perform generally better than W-cycles. This can however depend on the actual implementation of the solver, and the kind of grid geometries arising in other applications.

5.4. Parallel computing

The progress of distributed memory architectures over vector supercomputers has led to a regain of interest in iterative methods, as direct global

Figure 13: Effect of the multigrid schedule on the solver, for a simple disk-shaped domain test case where second-order multigrid boundary reconstruction does converge.

solvers such as FFT are particularly expensive in terms of inter-process communications. Iterative methods can often be adapted to distributed memory architectures, with little modification, and therefore remain simple to implement, while requiring limited communications.

A broad class of parallelization techniques for physical problems consists of splitting the computational domain into subregions, which are each managed and updated by a dedicated computing core. Such *spatial domain decomposition* techniques rely on the ability to update each CPU independently first, then address the couplings between different domains.

In RAMSES, this last step is implemented using buffer regions (see Fig. 14). Each computing core manages its own cells, but also possesses a local copy of cells from other neighboring CPUs which are needed for local computation. These buffer cells need to be updated after every iteration of the various iterative solvers used in the code. The update operation is done by communicating the updated values of the buffer cells from the CPUs which own them to the buffer regions in other processors. Therefore, any CPU only communicates with its direct neighbors, and the number of neighbors usually remains small. Moreover, the number of buffer cells scales only as a surface term, limiting the transfer to computation volume ratio. This is in contrast to the FFT, which requires a full transpose of the grid, and global all-to-all communications. In our multigrid scheme, we need to communicate both the solution and the residual for each the buffer cell between every Gauss-Seidel

Figure 14: Domain decomposition and buffer regions as used in RAMSES, in particular for the Poisson solver. The thick black line marks the boundary of the spatial domain decomposition between CPU 1 and CPU 2. CPU 1 owns all the red cells, while CPU 2 owns all the blue cells. In order to perform an update, each CPU needs the values of the fields in the immediate exterior vicinity of its domain (light red and light blue for CPUs 2 and 1 respectively). These buffer cells are updated after each iteration of the various solvers using inter-process communications.

sweep, and also after each restriction or prolongation operation.

We have performed weak and strong scaling timings of our multigrid Poisson solver in RAMSES. The strong scaling test case is a simple 256^3 cosmological simulation without any refinement (Cartesian grid), starting at 4 processes up to 512 processes. The weak scaling test scales from 256^3 with 4 processes to 2048^3 with 2048 processes. The test results are presented on Figure 15. We see that our parallel efficiency degrades down to 50% when we reach 32^3 cells per processor. Beyond this limit, we spend more time communicating data than updating the solution during each Gauss-Seidel sweep. We could improve our scaling by a factor of 2 by hiding surface cells communications by inner cells computations. The weak scaling tests shows that if we keep the computational load above 64^3 cells per processor, the scaling is almost perfect. This rule of thumb applies also for more complex grid geometries, although load balancing can degrade significantly in case of very deep adaptive time step strategies.

Figure 15: Strong (left panel) and weak (right panel) scaling test of our multigrid Poisson solver for a 256^3 Cartesian grid.

6. Conclusion

We have presented a simple and efficient multigrid algorithm for solving the Poisson equation on irregular domains defined on a regular Cartesian grid. This kind of problem frequently arises in AMR codes using a one-way interface strategy, and the method is therefore of particular interest for astrophysical applications with multiple adaptive time steps. Using a second-order reconstruction scheme for the boundaries of the multigrid levels, we have shown that our multigrid scheme features optimal convergence properties. Since we use a multigrid hierarchy orthogonal to the actual AMR grid, our memory requirements are minimal. In case of particularly complex boundary conditions, we have observed that our scheme fails to converge, an issue previously identified as the “small island” problem. We have designed a simple fix to this problem, degrading our multigrid boundary reconstruction accuracy to first-order. We have implemented this new technique in the RAMSES code, using a simple algorithm to determine “on the fly” which reconstruction technique should be used. We have shown the solver to be second-order accurate for the potential even in the presence of AMR levels, while the global force accuracy is close to second-order accuracy. Near level interfaces, the one-way interface scheme causes degradation of the force to first order, but only in very localized regions of codimension one. We have measured significant performance gains over our standard conjugate gradi-

ent solver, especially in the case of cosmological “zoom-in” simulations, where large fully-refined domains are present in the AMR grid. This simple and efficient multigrid solver could also be used for incompressible flow solvers, in presence of multiphase fluids or complex embedded solid boundaries.
